ABSTRACT

Recent work by Johnson, Moore and Ylvisaker (1990) establishes equivalence of the maximin distance design criterion and an entropy criterion motivated by function prediction in a Bayesian setting. The latter criterion has been used by Currin, Mitchell, Morris, and Ylvisaker (1991) to design experiments for which the motivating application is approximation of a complex deterministic computer model. Because computer experiments often have a large number of controlled variables (inputs), maximin designs of moderate size are often concentrated in the corners of the cuboidal design region, i. e. each input is represented at only two levels. Here we will examine some maximin distance designs constructed within the class of Latin hypercube arrangements. The goal of this is to find designs which offer a compromise between the entropy/maximin criterion, and good projective properties in each dimension (as guaranteed by Latin hypercubes). A simulated annealing search algorithm is presented for constructing these designs, and patterns apparent in the optimal designs are discussed.

1. INTRODUCTION

The setting for this paper is that of deterministic function approximation, a subject which has attracted increasing attention in the statistical community in recent years. We shall denote the function of interest by y, and say that it has arguments $x^{(1)}$, $x^{(2)}$, $x^{(3)}$, ... , $x^{(k)}$ written collectively as the k-vector x. The eventual aim is that of constructing an approximation or prediction of $y(x)$ for any $x \epsilon T$ where T is a defined domain or region of interest. In this paper we will limit consideration to $T = [0, 1]^k$, that is, we will suppose that the range of each function argument has been scaled to the unit interval, and that the joint region of interest is the k-dimensional unit cube.

In the kind of application that we consider here, y is often expressed as a computer model, hence the phrase *computer experiment*. In this context, y may be thought of as a scalar output (or some chosen scalar function of vector outputs) of the deterministic model which results from specified values of inputs x. When y is difficult to evaluate, e.g. requires considerable machine time on an advanced computer system, we may for practical purposes consider y to be an "unknown" function of the inputs, since classical analysis of the function is often impossibly complicated.

In this paper, we are interested in the design of a computer experiment, comprised of n evaluations of y at selected values of x, to serve as the basis for constructing an approximation of y which can be easily evaluated at input values for which the computer model has not been evaluated. Such a "cheap" surrogate for y is useful in computational activities which require many function evaluations, e.g. maximization or Monte Carlo simulation. Applied research in statistical approaches to the design and analysis of computer experiments for this purpose has been discussed by Sacks et al. (1989) and Currin et al. (1991).

The basis of our work is described in the latter reference, and follows in the spirit of fundamental work in Bayesian function prediction by, for example, Kimeldorf and Wahba (1970) and Micchelli and Wahba (1981). Basically, a "spatial" stochastic process or random function Y is defined over T as an initial expression of our uncertainty about y. Here, Y will be a stationary Gaussian process for which

$$\text{Corr}\,[Y(\mathbf{x}_s),\ Y(\mathbf{x}_t)] = R\,[d\,(\mathbf{x}_s,\ \mathbf{x}_t)],$$

i.e. correlation between two input values (or "sites", borrowing an intuitive term from geostatistics) is a function of some distance d defined between those two values. In this paper, we shall specifically consider rectangular and Euclidean distance, i.e.

$$d\,(\mathbf{x}_s,\ \mathbf{x}_t) = \sum_{l=1}^{k} |\, x_s^{(l)} - x_t^{(l)}\,| \quad \text{and}$$

$$d\,(\mathbf{x}_s,\ \mathbf{x}_t) = \left[\sum_{l=1}^{k} (x_s^{(l)} - x_t^{(l)})^2\right]^{1/2},$$

respectively. Once a design of n runs has been specified, and the corresponding evaluations of y made, completion of a prediction of y at any $\mathbf{x}$ is straightforward: Bayes' Theorem leads to a posterior process, which is also Gaussian, and squared error loss leads to the use of the posterior mean function (of $\mathbf{x}$) as the prediction or approximation, $\hat{y}(\mathbf{x})$. In addition, the variance or standard deviation of the posterior process at a particular site can be thought of as a measure of "predictive uncertainty" at that site.

The remainder of this paper is concerned with the construction of experimental designs for constructing function predictions, loosely motivated by the general prediction methodology just described.

2. AN OPTIMALITY CRITERION

Given a definition of distance, the following notation is useful in discussing our criterion for ranking designs. For a given design D, define a *distance* list $d = (d_1,\ d_2,\ \cdots,\ d_m)$ in which the elements are the distinct values of inter-site distances, sorted from the smallest to the largest. Hence m can be as large as $\binom{n}{2}$ or as small as 1. Also, define an *index* list $J = (J_1,\ J_2,\ \cdots,\ J_m)$, in which J_j is the number of pairs of sites in the design separated by distance d_j. Hence the sum of elements of J must be $\binom{n}{2}$.

Johnson, Moore, and Ylvisaker (1990) explored several connections between certain statistical and geometric properties of designs; in our context, one of their results can be

stated as follows. Let Y_θ, $\theta = 1, 2, 3, \cdots$, be a sequence of stationary Gaussian stochastic process over T, which differ only in that the correlation function for Y_θ is $R_\theta(x_s - x_t) = [R(d(x_s, x_t))]^\theta$. Here R is a fixed correlation function which must be decreasing in d. The result may then be briefly stated as follows: As θ tends to infinity, the designs that minimize the generalized variance of the posterior process at any finite collection of sites not observed are necessarily those for which $(1)d_1$ is maximized, and among the designs for which this is true, $(2)J_1$ is minimized. The authors referred to designs which have this property as maximin (Mm) designs of minimum index. The result then establishes a connection between the geometric Mm criterion, and what might be called a "D-optimal" prediction criterion in a limit as local correlations become weak.

Here, we shall extend the definition of a maximin design in a somewhat arbitrary but intuitively appealing manner as follows. Call D a maximin design if among available designs, it

   1a)   maximizes d_1, and among designs for which this is true,

   1b)   minimizes J_1, and among designs for which this is true,

   2a)   maximizes d_2, and among designs for which this is true,

   2b)   minimizes J_2, and among designs for which this is true,

        ...

   ma)   maximizes d_m, and among designs for which this is true,

   mb)   minimizes J_m.

Because requirements 1a and 1b alone specify Johnson, Moore, and Ylvisaker's definition of a Mm design, our more elaborate definition for Mm optimality essentially only breaks ties among multiple designs which would be Mm (and of minimum index) by their definition. Although this extended definition of Mm is intuitively appealing, we have not established connections between it and asymptotic statistical optimality of higher order.

In the following, it will be necessary to have a scalar-valued design criterion function which can be used to rank competing designs in such a way that the Mm design receives the

highest ranking. For this, we introduce a family of functions

$$\phi_p(D) = \left[\sum_{j=1}^{m} J_j d_j^{-1} \right]^{1/p} ,$$ (2.1)

where p is a positive integer, and J_j and d_j characterize the design D. Note that for large enough p, each term in the sum in (2.1) dominates all subsequent terms, and so from any design class, the designs that minimize ϕ are the Mm designs in that class. The issue of selecting a value of p for a given numerical search will be discussed later.

3. A CLASS OF DESIGNS

Although the Mm criterion has much intuitive appeal, and the work of Johnson, Moore, and Ylvisaker provide a sound theoretical justification for its use, there are certain characteristics of many unconstrained Mm designs which may not be desirable for computational experiments in practice. Consider, for example, the case in which $n = k+1$, and n is a multiple of 4. For these problems, it can be shown that orthogonal arrays such as Plackett-Burman designs are Mm for $T = [0, 1]^k$, with respect either to rectangular or Euclidean distance. However, it is often the case that only one or a few input variables have nonnegligible influence on y, and that the effects of these inputs can be nonlinear. In such circumstances, a two-level design "collapses" to yield only a few data points, with no response information at intermediate values of any input variable. Of course, the same can be said of many physical experiments; Box and Meyer (1986) use the phrase "effect sparsity" to describe physical experiments in which a relative few controlled factors are important. However, in physical experiments, y generally includes a random noise component, and a collapsed two-level design provides replication which is useful from the standpoint of estimation. Since (by our definition) computational experiments involve no random noise, even this benefit is lost in this context.

The work reported here is a first step toward developing computational experiment designs which are good both in situations of "effect sparsity" and in situations where all or most inputs are important. Here, we shall attempt to accomplish such a "compromise" by applying the Mm criterion within a class of designs for which each one-dimensional projection (i.e. "collapsed" image) is Mm, as follows. For each of the k design variables, the n scaled

values to be used in the experiment are elements of the set $V = \{0, 1/(n-1), 2/(n-1), \cdots, 1)\}$. The designs in the class to be investigated assign some ordering of these values to each input variable for the n runs in the experiment, i.e. each column of the n-by-k design matrix contains some permutation of these values. Where these permutations are selected randomly, the result is what Patterson (1954) called a lattice sample, and is a special case of what McKay, Conover, and Beckman (1979) called a Latin hypercube sample. Here, we will not discuss randomized design, but will use this structure as a class from which we hope to identify (fixed) Mm designs; we shall refer to these as maximin Latin hypercube (MmLh) designs. (Park (1991) also considered the class of Latin hypercube arrangements in an optimal design setting using a different selection criterion.)

4. A DESIGN CONSTRUCTION ALGORITHM

The algorithm described in Figure 1 is a version of the Metropolis algorithm, or "simulated annealing". (A discussion and example of the use of optimization by simulated annealing in statistical design problems is given by Bohachevsky, Johnson, and Stein (1986).) Briefly, a search begins with a randomly chosen Lh design, and proceeds through examination of a sequence of designs, each generated as a *perturbation* of the preceding one. In this case, a perturbation D_{try} of a "current" design D is formed by interchanging two randomly chosen elements within a randomly chosen column of the corresponding design matrix. (For simplicity, we shall use the notation D to denote both a design and its associated design matrix.) In the course of the search, any time a perturbation of the current design leads to an improvement, i.e. has a lower value of ϕ then the current design, it is adopted as the new current design from which the next perturbation is generated. If a perturbation of the current design leads to a worse design, a random decision is made either to discard the perturbation and retain the current design, or to replace D with D_{try}. In this case, replacement occurs with probability

$$\pi = \exp\{-[\phi(D_{try}) - \phi(D)]/t\}.$$

where t is an algorithm parameter known as the "temperature", a term which comes from the original physical motivation for annealing as an optimization process. Hence perturbations which lead to slightly worse designs (as measured by ϕ) are more likely to replace the current

9.) Stop and report D_{best}.

design than perturbations which lead to significantly worse designs. Also, a given increase in ϕ (decrement in design preference) is more likely to be accepted early in the search, when the temperature has a relatively high value, than it is later in the search as the temperature is "cooled". This randomized behavior is intended to provide a means by which the search may escape from designs which are only locally optimal, i.e. cannot be improved with respect to ϕ by any single perturbation. Throughout the search, the algorithm keeps track of the "best" design encountered to date, D_{best}. After a given number of perturbations have been tried at a given temperature without improving the best design, the temperature is lowered by a standard factor and the search continues. When, after a large fixed number of tries, no exchange of the current design for a perturbed design results in an improvement (lower value of ϕ) at a given temperature, the search is ended and D_{best} is reported.

In order to implement the annealing algorithm, the values of certain algorithm parameters must be set. As in most applications of annealing for optimization, we do this by a combination of experience and heuristic rules which seem to work well. Below, we list some brief guidelines which we currently use in setting these values.

Choice of t_0: This is the initial value of t, the temperature parameter. For rectangular distance, t_0 is chosen through a heuristic argument applied to a hypothetical design with a distribution of inter-site distances which is uniform between 50% and 150% of the average inter-site distance. This range can be determined before the search since average inter-site distance for this class of designs is completely determined by the values of n and k. The value of t_0 is then set so that a perturbation of this hypothetical design which decreases one of the currently smallest intersite distances by a small value δ would be accepted with high probability; we currently use $\delta = 1/(n-1)$, the smallest possible inter-site distance along any one coordinate axis. Specifically, we determine the value of t for which such a perturbation would be accepted with probability $\pi = 0.99$. A similar procedure is used for determining t_0 for a search involving Euclidean distance, except that in this case, we actually perform the search using the square of distance. The hypothetical design has a uniform distribution of squared Euclidean inter-site distances for which the average is determined by n and k, and we use $\delta = 1/(n-1)^2$ in selecting a

value for t_0. As mentioned above, these rules are heuristic, but seem to work fairly well in practice; other rules might be more effective. The goal is to begin with a temperature high enough so that the algorithm performs a nearly unbiased random walk among candidate designs early in the search, but not so high that it wastes too much time doing this.

Choice of FAC$_t$: This is the factor by which the temperature is modified, i.e. a value of 0.95 results in a 5% reduction in temperature. Values slightly less than one yield relatively slow decreases in temperature (relatively slow, relatively successful searches), while smaller values yield more rapid decreases (relatively fast, relatively less successful searches). We have not attempted to develop a reasonable rule-of-thumb for such values, but have used 0.90 and 0.95 with generally good results.

Choice of I_{max}: This parameter is the number of design perturbations the algorithm will try before going on to the next temperature, provided no new best design is found. Whenever a new best design is identified, the counter is reset so that I_{max} additional perturbations are tried at that temperature. It seems reasonable that I_{max} should be larger for larger problems, i.e. those for which the number of possible perturbations, $\binom{n}{2} \times k$, is relatively large. We have used about 10 times this number for the value of I_{max} in many optimizations.

5. CHOICE OF A SPECIFIC CRITERION FUNCTION (p)

The algorithm as outlined above is used to search for a design which is ϕ_p-optimal, for a specified value of p. Recall that the argument for use of ϕ_p as a criterion function is based on the fact that, *for large enough p*, it ranks designs for a given problem in the same way that the more cumbersome maximin criterion (statements 1a through mb) does. A practical issue is then how large p must be. Figure 2 displays the ranking of designs for the problem in which $n = 5$, $k = 3$, and rectangular distance is used, based both upon ϕ_p for three values of p, and ϕ_∞, i.e. the true maximin ranking. (A small problem is used here so that all 142

Figure 2: Comparison of Design Rankings by ϕ_p and Mm; Rectangular Distance, $n=5$, $k=3$
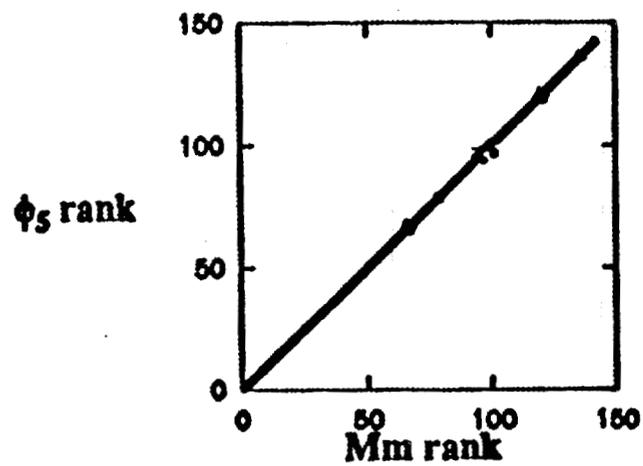

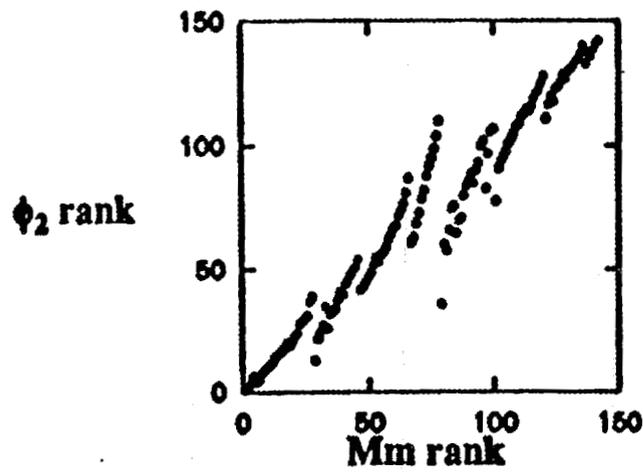

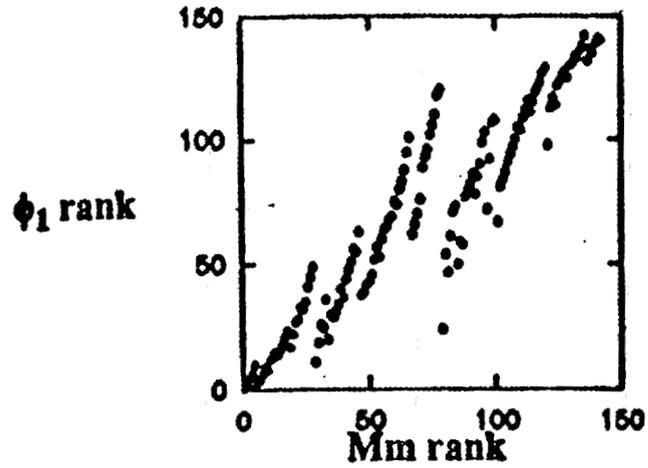

unique designs could be represented on the graphs.) In this case, when $p = 1$ the best design by the ϕ criterion does not coincide with the Mm design. For $p = 2$, although there is some difference between how designs are ranked, the two criteria rank the same design as best. Finally, it seems clear that p as small as 5 is sufficient for purposes of searching for an optimal design in this problem. This varies greatly with the specific problem, however. Often, but not always, larger problems (those defined by larger values of n and k) require values of p as large as 20 to 50 before the best design found ranks best with respect to both the Mm and ϕ criteria.

There is, however, another consideration regarding choice of p. The algorithm described above tends to more reliably find a design which minimizes ϕ_p when p is set to a relatively small value. Figure 3 contains a histogram showing the fraction of searches (out of 100 tries) which found the ϕ_p-optimal design when $n = 8$ and $k = 4$, for several values of p. Clearly, smaller values of p lead to greater success rates in this problem (and others). In this case, designs which minimized ϕ_p for each value of p examined also minimized ϕ_∞, i.e. even the ϕ_1-optimal design is a Mm design.

These two observations imply that the best value of p would be the smallest one for which ϕ_p and the Mm criterion agree at least on which design is best. In practice, this seems impossible to predict in advance. One can envision relatively straightforward heuristic sequential strategies which might "hone in" on a good value of p in a sequence of several optimizations; to date we have not tried this. Our current approach is to simply use the annealing algorithm to perform several searches at each of several values of p; we currently use $p = 1$, 2, 5, 10, 20, 50, and 100. The optimized design which is best with respect to the maximin criterion is selected as the single product of the exercise.

6. SOME RESULTS

The algorithm described above has been used to generate the catalog of MmLh designs listed in Appendices A and B, for Euclidean and rectangular distance, respectively. A catalogue of computed MmLh designs for each distance measure is listed in Appendices A and B for each combination of n between 3 and 12 and k between 2 and 5. Additional

Figure 3: Number of Times Mm Design is Found in 100 Attempts Using ϕ_p; $n=8$, $k=4$
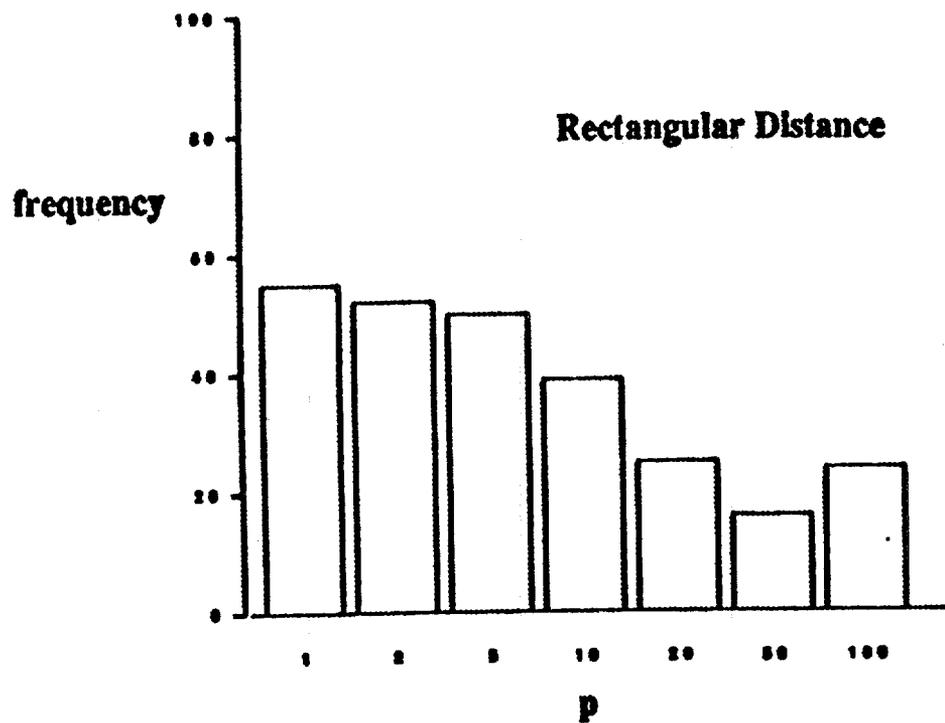

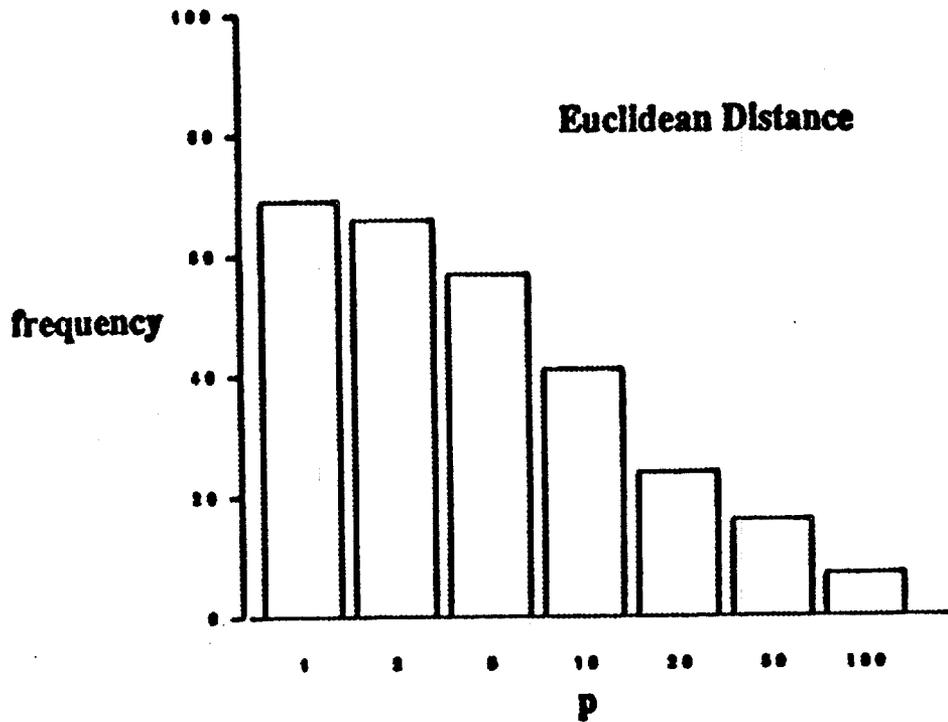

designs are listed for $k = 2$ (n through 20), $k = n$ (n through 9), and $k = n/2$ (n through 14). The algorithm described above was used in generating most of these designs. However, in some cases for which it was computationally practical, the design listed was found by complete search over all Latin hypercube arrangements; this was done for $k = 2$ with $n \le 11$, $k = 3$ with $n \le 6$, and $k = 4$ with $n \le 5$.

Tables 1.A and 1.B show the smallest value of p for which the apparently optimal design was found, and the fraction of tries at that value of p which resulted in that or an equivalent design. As can be seen from these tables, there are many cases in which the best design found was produced in only a small number of optimizations. In some of these cases, it may very well be that better designs exist.

Tables 2.A and 2.B contain values of the minimum distance between pairs of sites in each design, and the index J_1, i.e. the number of pairs of separation d_1. It is useful to remember that the largest possible distance between two sites is k for rectangular distance and $k^{1/2}$ for Euclidean distance.

Selected designs with $k = 2$ are graphed in Figures 4.A and 4.B for Euclidean and rectangular distances, respectively. The sites for these designs, particularly for larger values of n, are generally equally spaced along parallel lines; the Latin hypercube structure implies that these lines cannot be parallel with either axis. The designs displayed for $n = 17$ are identical for the two distance measures, and similar for $n = 9$, while the definition of distance seems to be more important for the designs of $n = 5$ and 13 points.

An interesting property shared by some of the designs is the tendency of design sites to be approximately or exactly equidistant from the center of T. For the designs computed here, this property holds primarily among those designs for which $n = k$ or $n = 2k$. Tables 3.A and 3.B give the minimum and maximum distances between a design site and the center of T for each design.

The designs for which $n = 2k$ have other interesting properties. In particular, all such designs tabulated, except in the case of $n = 14$ based on rectangular distance, are foldover designs. By this, we mean that the design can be partitioned into pairs of sites, each with the property that one site is the reflection through the center of T of the other site. Another interesting geometric property holds for several of these designs. If one site from each

foldover pair is eliminated, leaving an k-by-k design matrix, and each element of this reduced matrix is replaced by the absolute difference between the element and 1/2 (i.e. distance to the center of the region in one-dimensional projections), then the elements of the resulting matrix each take one of k unique values. Each of these values appears once in each row and once in each column of the matrix; that is, the design matrix reduced in this way contains k "symbols" in the pattern of a Latin square.

A similar pattern holds for the designs generated with $n = k = 3$ through 6, for either definition of distance. In these cases, if each element in the entire n-by-n design matrix is replaced by the absolute difference between the element and 1/2, the resulting matrix contains each unique value twice in each row and column for even n. For odd n, the result is the same except that the zeros (corresponding to elements which were 1/2 in the original design matrix) appear only once in each row and column.

We have not undertaken a thorough investigation of the geometric properties of these designs. However, we find the observations noted above to be interesting, and believe that further study might reveal "recipes" for maximin or near-maximin Latin hypercube designs which do not require extensive numerical searches.

7. SUMMARY

We have suggested the use of maximin Latin hypercube designs for computational experiments in which the general goal is the construction of an approximation or prediction of the deterministic scalar-valued output variable as a function of the input variables. Use of the maximin distance criterion is motivated by a result of Johnson, Moore and Ylvisaker (1990), who established an equivalence between the Mm property and a kind of D-optimality for Bayesian prediction, in a limit as local correlations are weakened. Since all Latin hypercube designs (unlike many unconstrained Mm distance designs) are evenly distributed in each one-dimensional projection, they are intuitively appealing for situations in which only one or few inputs have an important impact on the output variable. Since many computer models display this sort of effect sparsity, the "compromise" achieved by using the Mm criterion within the class of Latin hypercube arrangements may yield designs which are effective for predicting the output both when few or many inputs are important.

A criterion function, ϕ_p, and a numerical optimization procedure based on simulated

annealing have been presented for generating MmLh designs. A catalogue of designs produced by this algorithm is presented in the appendices to this report. Observations were made concerning some of the geometric properties of the MmLh designs generated, particularly in the cases of $k = 2$, $n = k$, and $n = 2k$.

EXTERNAL DISTRIBUTION

39. Professor Roger W. Brockett (EPMD Advisory Committee), Wang Professor of Electrical Engineering and Computer Science, Division of Applied Sciences, Harvard University, Cambridge, MA 02138.

40. Dr. N. N. Chan, Department of Statistics, Chinese University of Hong Kong, Shatin, N. T., Hong Kong.

41. Siddhartha Chatterjee, RIACS, Mail Stop T045-1, NASA Ames Research Center, Moffett Field, California 94035-1000.

42. Dr. John J. Dorning (EPMD Advisory Committee), Department of Nuclear Engineering Physics, Thornton Hall, McCormick Road, University of Virginia, Charlottesville, VA 22901.

43. Dr. Robert Easterling, Comp and Human Factors Division, Sandia National Laboratory, P. O. Box 5800, Albuquerque, New Mexico 87185.

44. Dr. Jerome Friedman, Department of Statistics, Sequoia Hall, Stanford University, Stanford, California 94305.

45. Prof. Mark Johnson, Department of Statistics, University of Central Florida, Orlando, Florida 32816-0370.

46. Dr. John F. Kitchin, Digital Equipment Corporation, 88 Reed Road HLO2-2/N04, Hudson, Massachusetts 01749-9987.

47. Dr. James E. Leiss (EPMD Advisory Committee), Rt. 2, Box 142C, Broadway, VA 22815.

48. Dr. Yong B. Lin, Department of Statistics, Ewha Womans University, Seoul 120-750, South Korea.

49. Dr. Michael McKay, Statistics Group A1, Los Alamos National Laboratory, MS F600, Los Alamos, New Mexico 87545.

50. Dr. James M. Minor, E. I. DuPont de Nemours and Co., P. O. Box 6091, Newark, Delaware 19714-6091.

51. Dr. Leslie Moore, Statistics Group A1, Los Alamos National Laboratory, MS F600, Los Alamos, New Mexico 87545.

52. Professor Neville Moray (EPMD Advisory Committee), Department of Mechanical and Industrial Engineering, University of Illinois, 1206 West Green Street, Urbana, IL 61801.

53. Dr. Vijayan Nair, Statistics Research, AT&T Bell Labs, Murray Hill, New Jersey 07974.

54. Dr. David Nelson, Scientific Computing Staff, Applied Mathematical Sciences, Office of Energy Research, U.S. Department of Energy, Washington, D.C. 20585.

55. Dr. Jerome Sacks, NISS, P. O. Box 14162, Research Triangle Park, North Carolina, 27709-4162

56. Dr. L. R. Shenton, Office of Computing and Information Services, Boyd Graduate Studies Building, University of Georgia, Athens, Georgia 30602.

57. Dr. Jyh-Jen Shiau, AT&T Bell Labs, P. O. Box 900, Princeton, New Jersey 08540.

58. Prof. Randy Sitter, Department of Mathematics and Statistics, Carleton University, Ottawa K1S5B6, Canada.

59. Dr. Daniel L. Solomon, Department of Statistics, North Carolina State University, P. O. Box 5457, Raleigh, North Carolina 27650.

60. Dr. Werner Stuetzle, Department of Statistics, GN-22, University of Washington, Seattle, Washington 98195.

61. Mr. Don X. Sun, Department of Statistics, University of Waterloo, 200 University Ave. W, Waterloo, Ontario N2L 3G1, Canada.

62. Mr. Boxin Tang, Department of Statistics, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada.

63. Dr. Ray A. Waller, S-1, Statistics, Los Alamos National Laboratory, P. O. Box 1663, Los Alamos, New Mexico 87545.

64. Professor Mary F. Wheeler (EPMD Advisory Committee), Rice University, Department of Mathematical Sciences, P. O. Box 1892, Houston, TX 77251.

65. Dr. D. George Wilson, Numerically Intensive Computing, Applications Support Center, Department 41UD, MS 276, Neighborhood Road, Kingston, New York 12401.

66. Dr. Kwan Y. Wong, IBM Almaden Research Center & SSPD, 650 Harry Road, K51/080, San Jose, California 95120.

67. Dr. C. F. Jeff Wu, Department of Statistics and Actuarial Science, University of Waterloo, Waterloo, Ontario N2L3G1, Canada.

68. Professor Henry Wynn, Department of Mathematics, The City University, Northhampton Square, London EC1V OHB, England.

69. Professor William Welch, Department of Statistics and Actuarial Science, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada.

70. Professor Don Ylvisaker, Department of Mathematics, University of California, Los Angeles, California 90024.

71. Office of Assistant Manager for Energy Research and Development, U.S. Department of Energy, Oak Ridge Operations Office, P. O. Box 2001, Oak Ridge, Tennessee 37831-8600.

72-81. Office of Scientific and Technical Information, P. O. Box 62, Oak Ridge, Tennessee 37831-0062.
